Evidence for the Cure of HIV Infection by CCR5Δ32/Δ32 Stem Cell Transplantation

Abbreviations
- cAMP: Cyclic Adenine Monophosphate; HSO: Hematopoietic Stem Cell; ICER: Inducible cAMP Early Repressor; CREM: Cyclic AMP Responsive Element Modulator; TFs: Transcription Factors; NFATc1: Nuclear Factor of Activated T Cell c1; nTreg: Naturally Occurring Regulatory T Cells; tTreg: Conventional CD4+ T Cells

Editorial

The unprecedented power of the hematopoietic stem cell (HSC) transplantation of the CCR5Δ32/Δ32 cells resistant to HIV has been proven to cure HIV infection in the case of leukemic patient (‘Berlin patient’ – Timothy Ray Brown) reported two years ago [1]. Since then another two cases proven to cure HIV infection after hematopoietic stem cell (HSC) transplantation of the CCR5Δ32/Δ32 cells were reported from Brigham and Women Hospital in Boston [2].

The Δ32 mutation at the CCR5 locus was found in Europe, with higher frequencies in the north [3]. Homozygous carriers of the Δ32 mutation (CCR5Δ32/Δ32) are resistant to HIV-1 infection because the mutation prevents functional expression of the CCR5 chemokine receptor used by HIV-1 to enter CD4+ T cells. The CCR5Δ32/Δ32 mutation is a good example of an advantageous allele with a well-characterized geographic distribution. The Δ32 mutation currently plays an important role in HIV resistance because homozygous carriers have reduced susceptibility to infection and delayed onset of AIDS, while homozygous carriers are resistant to HIV infection [4]. Ibuprofen was initially proposed as the selective agent, but the subsequent analysis suggested that a disease like smallpox is a more plausible candidate [5]. Lescot and Mercuri [6] suggested that the geographic distribution imply a Viking origin. In particular they proposed that the allele was present in Scandinavia before 1,000 to 1,200 years ago and then was carried by Vikings westward to Iceland, eastward to Rusia, and southward to central and southern Europe.

The feasibility of this concept (Figure 1) is based on novel insights of the protection from GvHD by elevated levels of cAMP through binding of HIV-1 envelope protein gp120 to human regulatory T cells (Tregs) (Figure 2) [8,9]. Tregs represent a unique T-cell lineage endowed with the ability to effectively suppress immune responses. Therefore, approaches to modulate Treg function in vivo could provide ways to enhance or reduce immune responses and lead to novel therapies. It is known for a long time that Tregs need to be activated to exert their suppressive function on bystander conventional CD4+ T cells (tTcons). However, it has remained elusive how activation of Tregs may occur effectively, as their suppression is not restricted and their antigen specificity may be different from the cells they suppress. Earlier reports on anti-cD4-mediated tolerance and Treg activation took advantage of the HIV gp120 protein having been a high-affinity ligand for CD4 and reported that gp120 – mediated activation of naturally occurring Tregs (nTregs) through CD4 was sufficient to turn on the suppressive activity in nTregs (Figure 2) [10]. CD4-mediated activation depends on Lck and low levels of cyclic adenosine monophosphate (cAMP) production and can be blocked by Src family kinase inhibitors and adenylyl cyclase inhibitors. Functional analysis of the effects of gp120-mediated activation of Treg in vivo in a GvHD model demonstrated that the Treg activation by gp120 through adenylyl cyclase could abolish the rejection [6]. The data on gp120 are very important in the context Treg-mediated suppression in vivo as a starting point for potential new therapies to ameliorate GvHD in the course of HSC transplantation of the cells resistant to HIV-1. Figure 1. Intracellular Immunization with Gene-Modified Hematopoietic Stem Cells

Long-lived, self-renewing, multilineage hematopoietic stem cells (HSCs) could be modified such that they and their progeny resist HIV infection. The host could thereafter be repopulated with a hematopoietic system (including CD4+ T and myeloid targets for HIV) that is resistant to the replication and spread of HIV.

Identification of RANTES, MIP-1α, and MIP-1β as the Major HIV-Suppressive Factors Produced by CD8⁺ T Cells

Fiorenza Cocchi,* Anthony L. DeVico, Alfredo Garzino-Demo, Suresh K. Arya, Robert C. Gallo,*† Paolo Lusso‡

Evidence suggests that CD8⁺ T lymphocytes are involved in the control of human immunodeficiency virus (HIV) infection in vivo, either by cytolytic mechanisms or by the release of HIV-suppressive factors (HIV-SF). The chemokines RANTES, MIP-1α, and MIP-1β were identified as the major HIV-SF produced by CD8⁺ T cells. Two active proteins purified from the culture supernatant of an immortalized CD8⁺ T cell clone revealed sequence identity with human RANTES and MIP-1α. RANTES, MIP-1α, and MIP-1β were released by both immortalized and primary CD8⁺ T cells. HIV-SF activity produced by these cells was completely blocked by a combination of neutralizing antibodies against RANTES, MIP-1α, and MIP-1β. Recombinant human RANTES, MIP-1α, and MIP-1β induced a dose-dependent inhibition of different strains of HIV-1, HIV-2, and simian immunodeficiency virus (SIV). These data may have relevance for the prevention and therapy of AIDS.

Genetic Acceleration of AIDS Progression by a Promoter Variant of CCR5

The CCR5 gene encodes a cell surface chemokine receptor molecule that serves as the principal coreceptor, with CD4, for macrophage-tropic (R5) strains of human immunodeficiency virus–type 1 (HIV-1). Genetic association analysis of five cohorts of people with acquired immunodeficiency syndrome (AIDS) revealed that infected individuals homozygous for a multisite haplotype of the CCR5 regulatory region containing the promoter allele, CCR5P1, progress to AIDS more rapidly than those with other CCR5 promoter genotypes, particularly in the early years after infection. Composite genetic epidemiologic analyses of genotypes bearing CCR5P1, CCR5-Δ32, CCR2-64I, and SDF1-3′A affirmed distinct regulatory influences for each gene on AIDS progression. An estimated 10 to 17 percent of patients who develop AIDS within 3.5 years of HIV-1 infection do so because they are homozygous for CCR5P1/P1, and 7 to 13 percent of all people carry this susceptible genotype. The cumulative and interactive influence of these AIDS restriction genes illustrates the multigenic nature of host factors limiting AIDS disease progression.

Key Points

- Molecular profiling was used to optimize an ex vivo modulation protocol with dmPGE₂ for UCB transplantation.
- Pulse treatment of UCB with dmPGE₂ is safe and may lead to accelerated UCB engraftment and preferential cord chimerism.

Umbilical cord blood (UCB) is a valuable source of hematopoietic stem cells (HSCs) for use in allogeneic transplantation. Key advantages of UCB are rapid availability and less stringent requirements for HLA matching. However, UCB contains an inherently limited HSC count, which is associated with delayed time to engraftment, high graft failure rates, and early mortality. 16,16-Dimethyl prostaglandin E₂ (dmPGE₂) was previously identified to be a critical regulator of HSC homeostasis, and we hypothesized that brief ex vivo modulation with dmPGE₂ could improve patient outcomes by increasing the “effective dose” of HSCs. Molecular profiling approaches were used to determine the optimal ex vivo modulation conditions (temperature, time, concentration, and media) for use in the clinical setting. A phase 1 trial was performed to evaluate the safety and therapeutic potential of ex vivo modulation of a single UCB unit using dmPGE₂ before reduced-intensity, double UCB transplantation. Results from this study demonstrated clear safety with durable, multilineage engraftment of dmPGE₂-treated UCB units. We observed encouraging trends in efficacy, with accelerated neutrophil recovery (17.5 vs 21 days, P = .045), coupled with preferential, long-term engraftment of the dmPGE₂-treated UCB unit in 10 of 12 treated participants. This study was registered at www.clinicaltrials.gov as NCT00890500. (Blood. 2013;122(17):3074-3081)

Abstract: Local production of macrophage inflammatory protein-1β (MIP-1β), a β-chemokine that blocks human immunodeficiency virus type 1 (HIV-1) entry into CD4+ CC chemokine receptor 5+ target cells, may be a significant factor in resistance to HIV-1 infection and control of local viral spread. The mechanisms governing MIP-1β expression in T cells, however, are not well understood. Our results suggest that MIP-1β RNA expression in T cells is dynamically regulated by transcriptional factors of the cyclic adenosine monophosphate (cAMP) responsive element (CRE)-binding (CREB)/modulator family. Transient transfection of primary human T cells with 5′ deletion and site-specific mutants of the human MIP-1β promoter identified an activated protein-1 (AP-1)/CRE-like motif at position –74 to –65 base pairs, relative to the TATA box as a vital cis-acting element and a binding site for inducible cAMP early repressor (ICER). Ectopic expression of ICER or induction of endogenous ICER with the cAMP agonists forskolin and prostaglandin E2 resulted in the formation of ICER-containing complexes, including an ICER:CREB heterodimer to the AP-1/CRE-like site and inhibition of MIP-1β promoter activity. Our data characterize an important binding site for the dominant-negative regulator ICER in the MIP-1β promoter and suggest that dynamic changes in the relative levels of ICER and CREB play a crucial role in cAMP-mediated attenuation of MIP-1β transcription in human T cells. J. Leukoc. Biol. 79: 378–387; 2006.
Approaches to modifying hematopoietic stem cells for HIV resistance (Kiem et al. Cell Stem Cell, 2012)
CCR5 genotyping, CCR5 expressing cells (wild type; the first lane) or cells with Δ32 mutation (heterozygous; the second lane) and cells homozygous for Δ32 mutation (CCR5Δ32/Δ32; the third lane) were detected using PCR. Genomic DNA was extracted from cells isolated from peripheral blood mononuclear cells and subjected to CCR5-specific PCR spanning the Δ32 region. To study the CCR5 gene variant in HIV target cells, genomic DNA was extracted and subjected to PCR amplification with primers for the CCR5 gene spanning the Δ32 region from nucleotide 826 to 1138 on the chromosome 3p21.31 (accession no: NM_000579). The expected fragments were 312 bp for the CCR5 wild-type (wt) and 280 bp for the Δ32 variant. These fragments (denoted by arrows) have been excised from the native acrylamide gel and individually sequenced to confirm exact location of Δ32 deletion.
Homozygous Defect in HIV Coreceptor CCR5 (Landau et al. 1996 Cell 86:367)

(A) The nucleotide sequences of wild-type CKR-5 derived from normal donor (above) and EU cDNAs (below) are shown. The nucleotide sequence from normal donor CKR-5 cDNA was determined for the complete 1055 bp coding sequence and found to be identical to that reported by Samson et al. (1996). The nucleotide sequence of 2 EU CKR-5 cDNAs were identical to wild-type over the complete coding region with the exception of a 32 bp deletion. Nucleotide sequence of the 200 bp region of CKR-5 encompassing the deletion was also determined for cDNAs derived from clones EU2.11, EU2.15, EU2.16, EU2.17, and EU3.1. Each contained the identical deletion with no additional nucleotide changes. Only the region flanking the deletion is shown. The deleted region (nt 794 to 825) is shaded. Amino acids encoded out of frame as a result of the deletion beginning at codon 185 are shown in italics. Nucleotide numbering (above) is from the first nucleotide of the reported CKR-5 sequence (Samson et al., 1996). Amino acid residue numbers are shown below.

(B) Oligonucleotide primers used for nucleotide sequencing of CKR-5 cDNA and detecting the deleted allele by PCR. The coding region is indicated by dark shading. Primers have been designated by nucleotide position at which they hybridize. Oligonucleotides used in PCR for detecting the deletion are shown as lightly shaded arrows. Oligonucleotides for cloning the full-length cDNA are shown at either end.

Peripheral CD4⁺ T cells have equivalent levels of Tregs in persons homozygous for the CCR5 variant Δ32

### CD127

- **CCR5Δ32/Δ32**: 7.6%
- **CCR5wt/Δ32**: 8.8%
- **CCR5wt/wt**: 7.0%

### CD25

- **CCR5Δ32/Δ32**: 1.1%
- **CCR5wt/Δ32**: 1.1%
- **CCR5wt/wt**: 1.4%

### Foxp3

- **CCR5Δ32/Δ32**: 1.1%
- **CCR5wt/Δ32**: 1.1%
- **CCR5wt/wt**: 1.4%
Tregs homozygous for the CCR5 gene variant Δ32 can be expanded *in vitro* tenfold after CD3/CD28 activation in the presence of exogenously added recombinant IL-2.

![Graph showing the expansion of Tregs homozygous for the CCR5 gene variant Δ32 over 7 days](image-url)
The concept of allogeneic stem cell transplantation of the cells resistant to HIV using a regimen to improve and modulate the function of regulatory CD4⁺ T cells (Tregs) favors suppressing graft-versus-host disease (GvHD) while retaining the benefits of graft-versus-leukemia (GvL) effect

• In order to enable hematopoietic stem cell (HSC) transplantation of the cells resistant to HIV we intend to create database of bone marrow (BM) donors as well as umbilical cord blood cells (UCB) homozygous for CCR5Δ32 mutation.

• Secondly, based on detailed knowledge of cyclic adenosine monophosphate (cAMP)-mediated suppression of alloreactive Tcons using Tregs harboring Δ32 mutation we will strive to improve Treg immunosuppression and optimize capacity of the HIV glycoprotein (gp) 120 to ameliorate GvHD.

• For umbilical cord blood cells (UCB) homozygous for CCR5Δ32 mutation we will utilize prostaglandin E₂ (PGE₂)-mediated mechanisms to facilitate allogeneic transplantation and/or downregulate CCR5 expression. Key advantage of this process is less stringent requirements for HLA matching and better engraftment of the cells resistant to HIV.
